Abstract

This document aims to provide people who have done an introductory programming course the skills required to write C++ programs.

1 Introduction

1.1 A second programming language

This document is aimed at those who have done two years of Java programming at UKZN. These Java courses introduced all loop constructions and many operators. Arrays and data structures were also introduced. All of this was done in an object oriented setting using Java classes.

However some issues such as software housekeeping (e.g. Makefiles) were glossed over and hidden behind IDEs. Others, such as templates and many things were not touched upon at all. Some of these newer things are easy conceptually, and fundamental to modern C++ programming, though implementation details can be complicated. The pay-off comes when you use the Standard Library - a library which exploits advanced C++ features to make life easy for the programmer.

C++ can be used in various ways: procedural (like Fortran or C) or Object-orientated (like Java). This document covers the techniques to support each of these programming paradigms, dealing with

- Namespaces
- Using classes to build new classes inheritance
- Abstract Classes and Templates
- Using the Standard Library
- Techniques useful when writing big, project-sized programs.

1.2 Web pages and Text books

To aid readability, the examples in the text are mostly code fragments. Full examples will be posted online at the module's homepage:

http://www.cs.ukzn.ac.za/ murrellh/ap

Some complete program examples are given in the in the appendix to this text. Most of these have been adapted from examples on the *Ira Pohl* website:

http://users.soe.ucsc.edu/pohl/

Many more complete examples are posted there.

A few programming exercises are suggested in this document. Any computing book will offer more.

Unless otherwise stated, the page numbers in the margin refer to:

Bjarne Stroustrup, The C++ Programming Language (third edition), AT&T, 1997.

You can get this book from the library or buy your own copy from amazon.

There are also many free books on C++ on the web. For extra reading material you can download from the advanced programming webpage:

Frank Brokken, C++ Annotations (version 6.5.0)

1.3 The UKZN Teaching labs

Advanced Programming students will either use **G21** or the honours lab. Students can code under Microsoft Windows or Linux.

1.3.1 Microsoft Windows

Here your compiler will be MinGw and your IDE will be Code::Blocks. The CodeBlocksManual can be downloaded from the course website.

1.3.2 Linux

Here your compiler is g++ and your IDE is Eclipse

1.4 Major project for 2010

At the end of this module you will construct a program that will be written written using a large library of C++ classes.

In this major project you will try to simulate water flowing over a terrain. As C++ doesn't have any graphics routines for this project you will make use of the image processing library CImg to do our graphics work.

your program must initialise a *terrain* and then dump water on it. At each iteration the water will flow downhill and the terrain with its current water profile will be re-rendered.

2 C++ programming constructs

2.1 Keywords

You haven't been introduced to all of these keywords before. Many you'll never need. They're included here for completeness because you can't use them for variable names, etc.

and	$\mathtt{and}_{-}\mathtt{eq}$	asm	auto	bitand	bitor
bool	break	case	catch	char	class
compl	const	$const_cast$	continue	default	delete
do	double	$dynamic_cast$	else	enum	explicit
export	extern	false	float	for	friend
goto	if	inline	int	long	mutable
namespace	new	not	$\mathtt{not}_\mathtt{eq}$	operator	or
or_eq	private	protected	public	register	$reinterpret_cast$
return	short	signed	sizeof	static	$static_cast$
struct	switch	template	this	throw	true
try	typedef	typeid	typename	union	unsigned
using	virtual	void	volatile	$\mathtt{wchar}_{-}t$	while
xor	xor_eq				

2.2 Built-in Types and Enumerations

There are integral types (char, short, int, long) which can be intended to hold signed (the default) or unsigned values. So for example "unsigned char c" creates a one-byte variable big enough to hold any integer from 0 to 255. There are also floating point types (float, double, long double).

If you want an integer variable to be restricted to containing just a few specific values you can create an enumerated type

```
enum user_type {ugrad, pgrad, staff, visitor};
user_type u;
```

creates an enumerated type called user_type. u can only be set to the values 0, 1, 2 or 3 (or equivalently - and preferably - ugrad, pgrad, staff or visitor). The values can be set explicitly; for example

```
enum user_type {ugrad=2, pgrad=7, staff=9, visitor=3};
user_type u;
```

Enumerated types can be used wherever integer types can be.

2.3 Operators

The lines of the table are in order of precedence, so 'a * b + 6' is interpreted as '(a * b) + 6'. When in doubt put brackets in!

The **Associativity** column shows how the operators group. E.g. '<' groups left to right, meaning that a < b < c is equivalent to (a < b) < c rather than a < (b < c). Both are pretty useless expressions - (a < b) evaluates to 1 or 0 depending on whether it's true or not.

Associativity	Operator
left to right	::
left to right	() [], ->, ., typeid, casts,
right to left	! (negation), ~ (bit-not)
	new, delete ++,, - (unary) , * (unary), & (unary), sizeof
right to left	(type)
left to right	*, /, % (modulus)
left to right	- +
left to right	<<, >>
left to right	<, <=, >, >=
left to right	==, !=
left to right	& (bit-and), (bit-or)
left to right	^ (bit-xor)
left to right	&& (logical and)
left to right	(logical or)
right to left	?:
right to left	=, +=, -=, /=, %=, >>=, &=
left to right	throw
left to right	,

2.4 Selection

2.4.1 if

. . .

```
if (i==3) // checking for equality; '!=' tests for inequality
   // no braces needed for a single statement
   j=4;
else{
  // the braces are necessary if the
  // clause has more than one statement
  j=5;
   k=6;
}
2.4.2 switch
// switch is like a multiple 'if'.
\ensuremath{//} The values that the switching variable is compared with
// have to be constants, or 'default'.
switch(i){
case 1: printf("i is one\n");
        break; // if break wasn't here, this case will
               // fall through into the next.
case 2: printf("i is two\n");
        break;
default: printf("i is neither one nor two\n");
        break;
}
```

2.5 Loops

Note that if you use the Standard Library's containers and vectors, explicit loops might not be needed very much.

2.5.1 while, do

```
...
while(i<30){    // test at top of loop
    something();
...
}
...
do {
    something();
} while (i<30); // test at bottom of loop
...</pre>
```

2.5.2 for

The 'for' construction in C++ is very general. In its most common form it's much like for in other languages. The following loop starts with i set to 0 and carries on while i<5 is true, adding 1 to i each time round.

```
for(int i=0; i<5; i=i+1){
    something();
}
...
The general form of 'for' is

for ([expression1]; [expression2]; [expression3])
    something();</pre>
```

where all the expressions are optional. The default value for expression2 (the while condition) is 1 (true). Essentially, the for loop is a while loop. The above for loop is equivalent to

```
expression1;  // initialisation
while (expression2){ // condition
    something();
    expression3;  // code done each iteration
};
```

E.g. the 2 fragments below are equivalent. 'i' is set to 3, the loop is run once for i=3 and once for i=4, then iteration finishes when i=5.

Within any of the above loop constructions, continue stops the current iteration and goes to the next and break stops the iterations altogether. E.g. in the following fragment 0 and 2 will be printed out.

```
int i=0;
while (i<5){
   if (i==1){
      i = i+1;
      continue;
   }
   if (i==3)
      break;
   printf("i = %d\n", i);</pre>
```

```
i=i+1;
}
```

If you want a loop which only ends when break is done, you can use 'while(true)' or 'for(;;)'.

2.6 Aggregation

Variables of the same or different types can be bundled together into a single obect.

2.6.1 arrays

Variables of the same type can be put into arrays.

```
char letter[50];
```

defines an array of 50 characters, letter[0] being the 1st and letter[49] being the last character. C++ arrays have no subscript checking; if you go off the end of an array C++ won't warn you.

Multidimensional arrays can be defined too. E.g.

```
char values[50][30][10];
```

defines a 3D array. Note that you can't access an element using values[3,6,1]; you have to type values[3][6][1].

The Standard Library offers various alternatives (vector, for example) which are often preferable to the basic arrays described above because

- They can be made to grow on demand
- Many routines for copying and modifying them exist.

2.6.2 structures and classes

Variables of different types can be grouped into a structure or a class.

```
class person {
    int age;
    int height;
    string surname;
};
person fred, jane;
```

defines 2 objects of type person each of 3 fields. Fields are accessed using the '.' operator. For example, fred.age is an integer which can be used in assignments just as a simple variable can.

Structure and Class objects may be assigned, passed to functions and returned, but they cannot compared, so continuing from the above fragment fred = jane; is possible (the fields of jane being copied into fred) but you can't then go on to do

```
if (fred == jane)
  fprintf(stderr, "The copying worked ok\n");
```

- you have to compare field by field.

Classes can contain member functions as well as data. The data can be made private so that other objects can't access it directly.

2.7 Pointers

Even if you don't use pointers yourself, the code you'll learn from is likely to have them. Suppose i is an integer. To find the address of i the & operator is used (&i). Setting a pointer to this value lets you refer indirectly to the variable i. If you have the address of a variable and want to find the variable's value, then the dereferencing operator * is used.

```
int i=0;
cout << i << " is at memory location " << &i << endl;

// The next statement declares i_ptr to be a pointer at
// an integer. The declaration says that if i_ptr is
// dereferenced, one gets an int.

int *i_ptr;
i_ptr = &i; // initialise i_ptr to point to i

// The following 2 lines each set i to 5
i = 5;
*iptr = 5; // i.e. set to 5 the int that iptr points to</pre>
```

Pointers aren't just memory addresses; they have types. A pointer-to-an-int is of type int*, a different type to a pointer-to-a-char (which is char*). The difference matters especially when the pointer is being incremented; the value of the pointer is increased by the size of the object it points to. So if we added

```
iptr=iptr+1;
```

in the above example, then iptr wouldn't be incremented by 1 (which would make it point somewhere in the middle of i) but by the length of an int, so that it would

point to the memory location just beyond i. This is useful if i is part of an array. In the following fragment, the pointer steps through an array.

Pointers are especially useful when functions operate on structures. Using a pointer avoids copies of potentially big structures being made.

```
typedef struct {
    int age;
    int height;
    string surname;
} person;

person fred, jane;

int sum_of_ages(person *person1, person *person2){
    int sum; // a variable local to this function

    // Dereference the pointers, then use the '.' operator to get the    // fields
    sum = (*person1).age + (*person2).age;
    return sum;
}
```

Operations like (*person1).age are so common that there's a special, more natural notation for it: person1->age.

2.8 Functions

```
The form of a function definition is
```

```
<function return type> <function name> ( <formal argument list> ) {
  <local variables>
```

```
< body >
E.g.
int mean(int x, int y)
{
int tmp;
tmp = (x + y)/2;
return tmp;
or, if the function is a member of class stats, ::, the scope resolution operator can
be used to specify which particular function of that name to access.
int stats::mean(int x, int y)
int tmp;
tmp = (x + y)/2;
return tmp;
}
You can provide default values for the trailing arguments. E.g.
int mean(int x, int y=5)
{
int tmp;
tmp = (x + y)/2;
return tmp;
}
int foo=mean(7)
is legal, setting foo to 6.
```

You can have more than function of a particular name provided that the compiler knows unambiguously which one is required for a function call, so the functions with identical names have to take different arguments or must only be visible one at a time. It's not enough for functions to differ only in the return type.

By default, the variables given to a function won't have their values changed when the function returns. In the following fragment number won't be increased to 6.

```
void add (int x)
{
    x = x+1;
}
int number = 5;
add(number);
```

When add(number) is called, the x variable is set to the current value of number, then incremented, but number is unchanged. The following slight variation that uses "call by reference" will increase number

```
void add(int& x)
{
    x = x+1;
}
int number = 5;
add(number);
```

2.9 Declarations

First, a note on terminology. A variable is *defined* when it is created, and space is made for it. A variable is *declared* when it already exists but needs to be redescribed to the compiler (perhaps because it was *defined* in another source file). Think of *declaring* in C++ like *declaring* at customs – admitting to the existence of something. In C++ you can only define a variable once but you can declare it many times.

C++ declarations are not easy to read. You shouldn't need to use complicated declarations so don't worry too much if you can't 'decode' them. Keep a cribsheet of useful ones The following examples show common declarations.

```
int *p
                    pointer to an int
int x[10]
                    an array of 10 ints
const int *p
                    pointer to a constant int
int * const p
                    a constant pointer to an int
int (*x)[10]
                    a pointer to an array of 10 ints
int *x[10]
                    array of 10 pointers to ints
int (*f)(int)
                   pointer to a function taking and returning an int
void (*f)(void)
                   pointer to a function taking no args and returning nothing
int (*f[])(int)
                    An array of pointers to a functions taking and returning an int
```

Note the importance of the brackets in these declarations. On the Teaching System the c++decl program can help. E.g.

2.10 Memory Allocation

Space is automatically set aside for variables when they are defined, but sometimes you don't know beforehand how many variables you'll need or just how long an array might need to be. The Standard Library copes with such situations but you may need to deal with things yourself.

The new command creates space "on the fly". new[] creates arrays. There are corresponding delete and delete[] calls.

```
int i; cout <<"Type an integer "; cin >> i; int *ia = new int[i];
```

creates an integer array of the required size that can be destroyed by

```
delete[] ia;
```

If there's not enough memory for new to provide what you want, it will cause a bad_alloc exception (see section 2.12 for details).

2.11 Scope and Namespaces

A namespace is like a class that has no functionality. Stroustrup uses them a lot. They're a way of controlling scope - the part of the program where the entity has a meaning. The more localised variables are the better. There's

- file scope entities can be made visible only to entities in the same file.
- function scope entities can be made visible only to the function they're created in.
- block scope delimited by '{' and '}'.
- class scope entities can be made visible only to the class they're created in.
- namespaces You can put an entity into a namespace by doing something like

```
namespace test {
  int i;
}
```

then using test::i to access the variable. The command "using namespace test" will make all the entities in the namespace available for the rest of the unit that the statement is in, without the "test::" being necessary. It's tempting to put "using namespace std" at the top of each file to access all the standard routines, but this "pollutes the global namespace" with many routine names you'll never use, so consider using more specific commands like "using std:string"

It's possible for a local variable to mask a global variable of the same name. If, in a function that has a local variable i you want to access a global variable i, you can use ::i, but it's better to avoid such nameclashes in the first place.

2.12 Exceptions

p.356

In C every call had to be checked for error values - which could double the code size. C++ exceptions are an alternative to traditional techniques when they are insufficient, inelegant, and error-prone. Three keywords are involved

try - specifies an area of code where exceptions will operate

catch - deals with the exceptional situation produced in the previous try clause.

 ${f throw}$ - causes an exceptional situation

When an exception is 'thrown' it will be 'caught' by the local "catch" clause if one exists, otherwise it will be passed up through the call hierarchy until a suitable catch clause is found. The default response to an exception is to terminate.

There are many types of exception - they form a class hierarchy of their own. Here just a few will be introduced.

```
try {
// code
}
// catch a standard exception
catch(std:exception& e){
    // order of the catch clauses matters; they're tried
    // in the given order
}
// catch all the other types
catch(...) {
// cleanup
    throw; // throw the exception up the hierarchy
}
```

Here's an example that sooner or later will produce an exception.

p.128

```
try{
  for(;;)
  new char[10000];
} catch(bad_alloc) {
  cerr << "No memory left";
}</pre>
```

A useful exception is $\mathtt{out_of_range}$ (header $\tt stdexcept \gt$), which is thrown by at() and by $\mathtt{bitset} \lt \gt : \tt operator[]()$.

Exception handling code can slow a program down even when no exceptions happen. The code size will also increase.

3 Object-orientated programming

Object-orientated languages support to a greater or lesser extent the following concepts

- Encapsulation (including in an object everything it needs, hiding elements that other objects needn't know about). This keeps data and related routines together and unclutters the large-scale organisation of the program. Each object has a 'public' set of routines that can be called, and these routines are all that other objects need to know.
- Inheritance (creating new types of objects from existing ones). Rather than having many seemingly unrelated objects, objects can be organised hierarchically, inheriting behaviour. Again, this simplifies the large-scale organisation.
- Polymorphism (different objects responding to the same message in different ways). Rather than having a different routine to do the same thing to each of many different types of objects, a single routine does the job. An example of this is how the + operator can be overloaded in C++ so that it can be used with new classes.

Using an Object-orientated language often means that

- program entities can more closely model real-world entities. As Stroustrup wrote, "For small to medium projects there often is no distinction made between analysis and design: These two phases have been merged into one. Similarly, in small projects there often is no distinction made between design and programming."
- complexity is more localised
- code re-use is easier

3.1 Classes

Classes are at the heart of C++'s object-orientation. Classes are created with data in them, and constructors (routines that are run when an object is created) and member functions are associated with a class.

3.2 Class member privacy

Class members can have 3 types of privacy

private - can be used only by member functions and friends

protected - like private except that derived classes have access to them too. Try not to use this - it can help performance but it breaks encapsulation.

public - available to any function.

By default class members are private. You often want the data to be private (so that they can't be tampered with from the outside) but the functions public (so that they can be called by other objects). If you want other objects to be able to change the data, write a member function that the objects can call and make sure that the member function does validity checking. Then other member function that use the data won't have to check for validity first.

A private function is often called a helper or utility function because its for the benefit of other member functions. Note that a member function

p.278

- 1. can access private data
- 2. is in scope of class
- 3. must be invoked on an object

If you have the choice of writing a friend or member function, choose a member function.

p.280

Note that structs have no private or protected parts.

3.3 Friend classes and functions

It is sometimes useful to let the functions of one class have access to the components of another class without making the components public and without the overhead of having to call member functions to get private data.

The following shows how one class (in this case Another) can let another class (in this case Base) be a "friend" class

```
class Another { friend class Base; int value; ... }
```

For the sake of clarity it's a good idea to have the friend lines at the start of the class definition. Note that friendship is granted by the class being accessed, not claimed by the class wanting access.

A friend may be a non-member function, a member function of another class, or an entire class. Friends and derived classes differ in that derived classes might not be able to access all the members of the base class.

3.4 A complete example

The intTree class, given in the appendix, is an example of a class built from scratch. The intTree class makes use of a binary node class, bnode to hold and integer and a count and pointers to left and right branches of a binary tree. intTree has a constructor, intTree, and three member functions, find, insert and print.

The code shown here has no *destructor* defined. As an exercise try to find out what happens to memory after repeated use of intTree and insert the appropriate destructors to rectify matters.

3.5 Derived classes

The more you use C++ the more you'll be developing classes which require greater sophistication. Often you'll need to add extra functionality to an existing class. C++ provides a mechanism to build new classes from old ones

```
class More : public Base {
int value;
...
};
```

Here More inherits the members of Base. The public keyword means that the members of Base are as accessible to More as Base allows. By default derivation is private (which means that even Base's public members can't be accessed by More), but usually derivation should be public, privacy being control by the base class.

Coplien, p.103

When an object of type More is created, first the Base constructor is called, then More's constructor. When the object is destroyed, the destructors are called in reverse order. The constructors/destructors are not inherited, but you can say

```
More::More(int sz):Base(sz){}
```

passing arguments to a base member class constructor (or to a number of constructors using a comma-separated list).

A derived class can be assigned to any of its public base classes, so the following is possible

```
class More : public Base {
int value;
...
};
Base b;
More m;
b=m;
```

It will fill the fields of b with the corresponding values in m. However, m=b isn't possible.

You can derive new classes from a derived class, and you can derive many different classes from a base class so you can develop a family tree of related classes. As we'll see soon, the "parent" classes can keep parts of themselves private, not only to unrelated classes but to derived classes too.

Big classes don't necessarily imply big objects: all objects of a class share member functions, for instance.

It's possible for a class to be derived from 2 or more other classes. It's called Multiple Inheritance but it introduces complications, so don't use it unless you know what you're doing.

3.6 Static members

p.228

A static member is part of a class, but not part of an object of a class, so there's only one instance of them however many objects of that class are created. This is useful if, for instance, you want to keep a count of how many objects are created. A static member function

- 1. can access private data
- 2. is in scope of class
- 3. but can't be invoked on an object objectname.staticmemberfunction() is impossible.

3.7 Const members

p.229

The value of a const data member can't be changed. A const member function can't change the data of the class.

```
int day() const { return d};
```

doesn't modify state of the class.

3.8 Static Const members

Details regarding how to initialise static const members changed late in the C++ specification. A static const data member of integral or enum type can be initialized in the class definition, but you still need to provide another definition (without an initializer) for it. So

```
class C {
  const static int csi = 5;
};
const int C::csi;
```

is legal, but you can't do the same for floats, non-statics or non-consts. With some old compilers you have to initialise outside the class.

3.9 Overriding behaviour

As well as adding members a derived class can override behaviour simply by redefining a member function. For instance, if you are developing objects for a graphics editor, you'd like each kind of object to have a draw function, but you'd like each kind of object to have its own version.

Later (section 5) more details of class derivation will be described.

3.10 Templates

A class template is a "type generator": a way to fabricate many similar classes or functions from one piece of code. This is how the Standard Library can support many types of vector, etc. C++'s Templates are parameterized types. They support generic programming by obviating the need for explicit switch statements to deal with various data types. Let's look at an example. The following code swaps 2 integers in the usual C++ way

```
void swap (int& a, int& b) {
   int tmp = a;
   a = b;
   b = tmp;
}
```

If you wanted to swap other types of variables (including those you've defined) you could copy this code, replacing int by (say) float. But in situations like this, where the code is potentially generic, templates can be used.

```
template <class T>
void swap (T& a, T& b) {
   T tmp = a;
   a = b;
   b = tmp;
}
```

Here the "T" name is arbitrary (like a formal parameter in a function definition) and the class keyword can be replaced by the newer typename keyword. Note that the function is written much as before. When the compiler is now given the following code

```
int a = 3, b = 5;
float f=7.5, g=9.5;
swap (a, b);
swap (f, g);
```

it will create a version ("instantiation") of swap for each type required. These versions have nothing in common except that they were created from the same template - they won't share members, not even static ones. Templates are an example of source code re-use not object code re-use.

You can have template functions, but also template classes and derived classes. In the appendix we give a full listing, genTree.cpp, of the template version of the binary search tree. The programmer can now create a binary search tree of integers, characters, strings or any other data type provided a comparator function is available.

As an exercise, make use of the genTree class to count the occurrences of ascii characters in any text file. Then adapt your program to count word usage in any text.

4 The Standard Library

The Standard Library includes container classes: classes whose purpose is to contain other objects. There are classes for vectors, lists, etc. Each of these classes can contain any type of object (as long as the object can be copied safely - if it can't, use pointers to elements instead). You can, for example, use a vector<int> (meaning 'a vector of ints') in much the same way as you would use an ordinary C array, except that vector eliminates the chore of managing dynamic memory allocation by hand.

p.466

```
\label{eq:vector} $$ \ \ v(3); \ // \ Declare a vector (of size 3 initially) of ints $$ \ v[0] = 7; $$ \ v[1] = v[0] + 3; $$ \ v[2] = v[0] + v[1]; \ // \ v[0] == 7, \ v[1] == 10, \ v[2] == 17 $$ \ v.push_back(13); \ // \ add \ another \ element - the vector has to expand $$
```

Note the use of the push_back function - adding elements this way will make the container expand.

The Standard Library also includes about 70 algorithms that manipulate the data stored in containers - reverse, insert, unique, transform etc. Note that these operations act on the elements without explicit use of loops.

To use these features you need to include the corresponding header file. For example, #include <vector> is needed for vectors.

Read the Standard C++ Library Class Reference.

4.1 Iterators

Iterators are like pointers. They save algorithm writers the worry of having to deal with the internals of containers. They come in various types: random access, bidirectional, forward, reverse, input, output. They can be const. Some containers support only some Iterator types (you can't for example randomly access a list). See the documentation for details.

4.2 Strings

In older C++ books and in C books, strings are arrays of characters - C-style strings. Except when speed is vital, C++ strings are preferable to these. For some operators (concatenation, for example) strings may be a lot faster than C's character arrays. Also

- They grow on demand
- The Standard Library algorithms work on them
- Other containers use them
- Natural constructions like s=s1+s2; are possible

String objects have many features in common with other Standard Library objects. Since strings are familiar to you, it's useful to look at the facilities in more detail to prepare you for other Standard Library components.

4.2.1 Iterators

The following routines provide iterators (pointers) of various kinds, depending on whether you want to go forwards or backwards through the string and whether you want to change the string. The same kind of routines exist for vector etc.

```
// Iterators - note the various types
iterator begin();
const_iterator begin() const;
iterator end();
const_iterator end() const;
reverse_iterator rbegin();
const_reverse_iterator rbegin() const;
reverse_iterator rend();
const_reverse_iterator rend() const;
```

4.2.2 Size

These routines (similar ones exist for other containers) give you size information. p.456 reserve() doesn't change size or initialize elements - resize() does. capacity() - size() = reserved size.

```
// Capacity
  size_type
                size() const;
  size_type
                length() const;
  size_type
                max_size() const;
  void
                resize(size_type, charT);
  void
                resize(size_type);
  size_type
                capacity() const;
                 reserve(size_type);
  void
                  empty() const;
  bool
```

4.2.3 Routines

These string-specific routines (only a selection is shown below) provide the functionality that C people are used to. The names aren't too hard to remember, and the default arguments are reasonable. The routines are overloaded, so find can be used to look for strings, characters or even C-strings.

Note also that the c_str routine returns a C string.

```
const charT* c_str() const;
size_type find(const basic_string&,
               size_type = 0) const;
size_type find(charT, size_type = 0) const;
size_type rfind(const basic_string&,
                size_type = npos) const;
size_type rfind(charT, size_type = npos) const;
size_type find_first_of(const basic_string&,
                        size_type = 0) const;
size_type find_last_of(const basic_string&,
                       size_type = npos) const;
size_type find_first_not_of(const basic_string&,
                            size_type = 0) const;
size_type find_last_not_of(const basic_string&,
                           size_type = npos) const;
basic_string substr(size_type = 0, size_type = npos) const;
int compare(const basic_string&) const;
int compare(size_type, size_type, const basic_string&) const;
```

The case history (section ??) has many examples of string usage. Here are 2 short programs -

```
#include <fstream.h>
#include <string>

int main()
{
   string s1= "pine";
   string s2= "apple";
   cout << "length of s1 is " << s1.length() << endl;
   string s3= s1+s2;
   cout << "s1 + s2 = " << s3 << endl;
   string s4= s3.substr(2,4);
   cout << "s3.substr(2,4)=" << s4 << endl;

cout << "s3.find(\"neap\")=" << s3.find(\"neap") << endl;
   cout << "s3.rfind('p')=" << s3.rfind('p') << endl;
   return 0;
}</pre>
```

To get a line of text (that may include spaces) from the user, do

p.30

```
#include <fstream.h>
#include <string>

int main()
{
   string str;
   cout <<"Type a string\";
   getline(cin,str);
   cout <<"you typed" << str << endl;
   return 0;
}</pre>
```

4.3 vector p.447

Standard Library Vectors can have various element types and like other containers can be initialised in various ways:

```
vector <int> v; // an empty integer vector  
vector <int> v(5); // 5 elements, initialised to the default  
// value of the elements, in this case 0.  
// Vector resizing is expensive, so set to  
// the max size if you can.  
vector <int> v(5,13); // 5 elements initialised to 13  
vector <int> w(v.begin(),v.end()); // initialised from another container.
```

Many routines are available for vectors. For example, if you have a vector of strings, p.452 you can remove all the strings beginning with 'p' by doing the following

```
sort(fruit.begin(), fruit.end());
// create an iterator p1 for use with a vector of strings
// and set it to point to the first string to remove
vector<string>::iterator p1=
    find_if(fruit.begin(), fruit.end(), initial('p'));
// create and set p2 to point to the first string after
// those that begin with 'p'
vector<string>::iterator p2=
    find_if(p1, fruit.end(), initial_not('p'));
// Now erase
fruit.erase(p1, p2);
```

Note that you can't do the following (searching from each end of the vector) because forward and reverse iterators are different types, and you can't use erase with mixed types.

```
sort(fruit.begin(), fruit.end());
vector<string>::iterator p1=
        find_if(fruit.begin(), fruit.end(), initial('p'));
vector<string>::reverse_iterator p2=
        find_if(fruit.rbegin(), fruit.rend(), initial('p'));
fruit.erase(p1, p2);
```

These above examples use the standard algorithms, which are always useful as a fallback option, but the vector class has a more specialised routine which is likely to be faster

```
fruit.remove_if(initial('p'));
```

p.454

p.51

Remember that

- vector elements can move! insert, for instance, changes its 1st argument.
- vector doesn't have arithmetic operations: valarray (which is described later) does.

• vector doesn't have range-checking by default.

4.4 Queues

Variations include p.478??

- deque (pronounced deck) double-ended queue. One of the basic containers.
- queues items are pushed into the back of the container and removed from the front. The underlying container can be vector or a deque. The items can be whatever you like.

```
// create a message structure
struct Message{ ... }
```

```
// wait until an item appears on the queue, then process it.
void server(queue<Message> &q)
{
   while(!q.empty()) {
     Message& m = q.front();
     m.service();q.pop();
   }
}
```

• priority queues - items are pushed into the back of the container and removed from the front in order of priority. The underlying container can be vector, amongst other things. In the following example the priority is determined by comparing the value of the integers in the queue using less.

```
#include <queue>
#include <vector>
#include <iostream.h>
int main()
  // Make a priority queue of int using a vector container
 priority_queue<int, vector<int>, less<int> > pq;
  // Push a couple of values
  pq.push(1);
  pq.push(7);
 pq.push(2);
 pq.push(2);
  pq.push(3);
  // Pop all the values off
  while(!pq.empty()) {
    cout << pq.top() << endl;</pre>
   pq.pop();
return 0;
}
```

4.5 list

Lists are useful when items are likely to be inserted/deleted from the middle of long sequences. This example creates a vector then copies it into a list, reversing as it does so.

```
#include <vector>
#include <list>
#include <algorithm>
#include <iostream.h>

int main()
{
  vector<int> V;
  V.push_back(0);
  V.push_back(1);
  V.push_back(2);
```

```
list<int> L(V.size());
reverse_copy(V.begin(), V.end(), L.begin());
exit(0);
}
```

4.6 map

A map stores a mapping from one set of data (e.g. Names) to another (e.g. Phone numbers). The following example shows how to set up an "associative array" – an array where you can use a string as an index. It records how many times each word appears on cin, the standard input.

```
int main()
{

string buf;
map<string, int> m;
while (cin>>buf) m[buf]++;
  // write out result (see next example)
}
```

A map keeps items in order and has no duplicate keys. Variations include

p.478??

- hash_map an unsorted map.
- multi_map can have duplicate keys
- set a map with ignored values

p.483

```
// read in lines of the form
// red 7
// blue 3
// red 4
void readitems(map<string, int>& m)
 string word;
 int val=0;
      while(cin>>word>>val) m[word]+=val;
int main()
map<string, int>tbl;
readitems(tbl);
int total=0;
// We want to create an iterator p for use with this type of map.
// Since we're not going to change the map values using it,
// we'll make a const_iterator. We could do this using
     map<string, int>::const_iterator p
// but if we wanted to create other iterators of this type
```

```
// it would be tedious. So we use 'typedef' to make 'CI' a
// shorthand for the long expression.

typedef map<string, int>::const_iterator CI;
  for (CI p=tbl.begin(); p!=tbl.end(); ++p) {
     total+=p->second;
     cout<<p->first << '\t' << p->second << '\n';
  }
  cout << "total\t" << total << endl;
  return !cin;
}</pre>
```

Here's a fragment using multimap showing how to print out all the values associated a particular key (in this case the string "Gold"). It uses typedef as in the above example, and the useful equal_range function which returns an iterator to the first and last elements with a particular key value. Pairing up variables is so common that a facility called pair declared in the <utility> file is available to assist in their creation. The pair used here holds 2 iterators, but it can hold 2 items of different types too.

```
void f(multimap<string,int>&m)
{
typedef multimap<string, int>::iterator MI;
pair <MI,MI> g = m.equal_range("Gold");
  for (MI p=g.first; p!=g.second; ++p) {
      // print the value out
  }
}
```

In maps, m["blah"]=1; overwrites, m.insert(val) doesn't.

4.7 bitset

This provides efficient operators on bits.

```
#include <iostream.h>
#include <stdio.h>
#include <bitset>

int main()
{
    const unsigned int width = 32;
    bitset<width> b1("10111");
    bitset<width> b2 = 1023;
    bitset<width> b3;
    cout << "Type in a binary number (type a non-binary digit to end) ";
    cin >> b3;
    cout << "You typed " << b3 << endl;
    cout << "b2 flipped=" << b2.flip() << endl;
    cout << "b1=" << b1 << endl;
    return 0;
}</pre>
```

4.8 valarray

v2 = v2 * cos(v3);

p.663

valarrays are designed for doing fast vector calculations. They can be initialised in various ways

A slice is what you get when you take every nth element of a valarray. This is especially useful if the valarray represents the values in a 2D array - slices are the rows or columns. A slice needs to know the index of the first element, the number of elements and the 'stride' - the step-size.

// filling the spaces with elements that have fallen off

```
slice_array<double>& v_even= v2[slice(0,v2.size()/2,2);
slice_array<double>& v_odd= v2[slice(1,v2.size()/2,2);
v_odd *=2; // double each odd element of v2
```

// the other end

A gslice lets you extract subarrays from a valarray that represent the values in a p.677 2D array.

A mask array lets you pick out arbitrary elements. It needs to contain bool values p.678 and shouldn't be bigger than the valarray it's used with. When used as a subscript, the valarray elements corresponding to the true elements of the mask array will be chosen.

```
bool b[]= { true, false, true, true};
valarray<bool>mask(b,4);
valarray<double>v4= v[mask];
```

There's also an indirect array.

p.679

valarrays are built for speed - they aren't intended to grow, and operations aren't error-checked - if you multiply together 2 valarrays of different lengths the behaviour is undefined.

4.9 Algorithms

p.57

p.59

Algorithms (in <algorithm>) operate on containers, including strings. They may not always be the fastest option but they're often the easiest. They fall into 6 groups

- Search algorithms search(), count_if(), etc.
- Sorting algorithms sort(), merge(), etc.
- Deletion algorithms remove(), unique(), etc.
- Numeric algorithms partial_sum(), inner_product(), etc.
- Generation algorithms generate(), for_each(), etc.
- Relational algorithms equal(), min(), etc.

Algorithms usually take as their first 2 arguments iterators to mark the range of elements to be operated on. For example, to replace 'A' by 'B' in a string str one could do

```
replace(str.begin(), str.end(), 'A', 'B');
```

Here's one way to count how many instances of a particular character there are in a string using the find algorithm.

```
int count (const string& s, char c)
{
  string::const_iterator i=find(s.begin(), s.end(),c);
  int n=0;
  while(i!=s.end()){
    ++n;
    i=find(i+1, s.end(),c);
  }
  return n;
}
```

Here's a way to count the number of 'z' characters in a C-style string using the count algorithm. Note how the character array can be used like other containers.

oid g(char cg[] int gz)

```
void g(char cs[], int sz)
{
  int i1 = count(&cs[0], &cs[sz], 'z');
}
```

Here's the count algorithm again, this time being used to find a particular complex number in a list.

```
void f(list<complex>&lc)
{
int i1 = count(lc.begin(), lc.end(), complex(1,3));
}
```

Other algorithms include next_permutation and prev_permutation

```
int main()
{
  char v[]="abcd";
    cout << v << '\t';
  while (next_permutation(v, v+4))
        cout << v << '\t';
}

random_shuffle,

char v[]="abcd";
  cout << v << '\t';
  for (int i=5;i;i--) {
    random_shuffle(v, v+4);
    cout << v << '\t';
  }

and a routine to cycle elements

rotate (first, middle, last)</pre>
```

rotate "swaps" the segment that contains elements from first through middle-1 with the segment that contains the elements from middle through last.

4.10 Set algorithms

Set algorithms include

- includes()
- set_union()
- set_intersection()
- set_difference()
- set_symmetric_difference()

The following, while demonstrating some of these routines, uses 2 ideas that are often useful

• an output stream can be thought of as a container, so you can "copy" other containers onto it. The line

```
copy(s1.begin(), s1.end(), ostream_iterator<int>(cout, " "));
```

also puts spaces between the integers being printed. For now, don't worry if you don't understand the mechanics - it's useful so just use it!

• Sometimes you won't know how many resulting elements will be produced by an operation, you just want them all added to a container. inserter (which calls the container's insert() routine), front_inserter (which calls the container's push_front() routine - which vectors for example don't have) or back_inserter (which calls push_back()) do that for you.

```
#include <algorithm>
#include <set>
#include <iostream.h>
#include <iterator> // needed for ostream_iterator
int main()
{
  //Initialize some sets
  int a1[10] = \{1,2,3,4,5,6,7,8,9,10\};
  int a2[6] = \{2,4,6,8,10,12\};
  set<int> s1(a1, a1+10), s2(a2, a2+6), answer;
  cout << "s1=":
  copy(s1.begin(), s1.end(),
      ostream_iterator<int>(cout," "));
  cout << "\ns2=";
  copy(s2.begin(), s2.end(),
       ostream_iterator<int>(cout," "));
  //Demonstrate set difference
  set_difference(s1.begin(), s1.end(),
                 s2.begin(), s2.end(), inserter(answer,answer.begin()));
  cout << "\nThe set-difference of s1 and s2 =";</pre>
  copy(answer.begin(), answer.end(),
       ostream_iterator<int>(cout," "));
  cout << endl:</pre>
  return 0;
```

4.11 Using member functions

p.311

Algorithms can use the member functions of objects they're manipulating.

```
void print_list(set<Employee*>& s)
{
for_each(s.begin(), s.end(), mem_fun(&Employee::print));
}
```

4.12 Predicates

Some algorithms can be given a function to modify their behaviour. For example, the find_if algorithm can find items that conform to a particular condition as specified by a function. A predicate is a function object (an object that behaves like a function) that returns a bool showing whether or not an item matches the condition.

p.515

4.12.1 Creating predicates

<functional> supplies common conditions that can operate on various types: e.g.,
greater_equal<int>(), plus<double>(), logical_or<int>() etc. The following
does a vector multiplication of a and b, putting the answer in res to which elements
are added one at a time.

```
void discount(vector<double>& a, vector<double>& b, vector<double>& res)
{
transform(a.begin(), a.end(), b.begin(), back_inserter(res), multiplies<double>());
// vector multiplication
}
```

4.12.2 Adapters

p.518

Note: These are sometimes useful but look complicated, so don't worry if you don't understand them..

Adapters are ways to adapt existing predicates - they take and return a function that we can then use with Standard Library algorithms. There are 4 types -

binder - to use a 2-arg function object as a 1-arg function. less is a binary predicate. If we want make a unary predicate from it we can do bind2nd(less<int>(),7)).

```
member function adapter - to use a member function
```

p.520

pointer to function adapter - to use a pointer to a member function

negator - to negate an existing predicate

These can be combined -

```
... find_if ( ..... not1(bind2nd(ptr_fun(strcmp), "funny")));
```

5 More on Classes

Concrete Classes are the simple classes that behave just like int, char, etc once p.247 they're set up.

To make best use of Classes it's sometimes useful to redefine the operators as well as define member functions. For instance, if you were going to invent a class to deal with strings, it would be nice for '+' to join strings together. Or if you wanted to add range-checking to arrays, you'd have to modify the [] behaviour. Below are some examples of overloading, but first more on the mechanism of inheritance.

5.1 Virtual members

As mentioned earlier, it's easy to redefine a base class's function in a derived class, but to fully exploit polymorphism (the ability to deal with many types transparently), a new concept needs to be introduced.

Suppose that we were designing a graphics editor. We might have a base class Shape and various derived classes Triangle, Rectangle, etc, each with their own print member function. We'd like to collect these objects together into groups sometimes. An array of pointers to the objects would be appropriate, but what sort of pointers could we use? Fortunately, it's possible to assign a derived class pointer to a base class pointer, so the following is possible, creating an array of pointers to the base class.

```
Triangle t1, t2;
Rectangle r1, r2;

typedef ShapePtr Shape*;
vector<ShapePtr> shapes(4);
shapes[0]=&t1;
shapes[1]=&r1;
shapes[2]=&t2;
shapes[3]=&r2;
```

Then we could draw all the shapes in the group by calling the **print** function of each element. But there's a problem - because the elements are pointers to Shape, it's Shape's **print** function which is called, rather than the appropriate derived object's function.

The solution to this is to define print in the base class as a virtual function by having something like

```
virtual void print();
```

which lets us deal with the shapes array without having to worry about the real type of each component; the derived object's print function will always be called.

5.2 Abstract Classes

p.313

Some classes represent abstract concepts for which objects cannot exist. The functions *have* to be defined in the derived classes. Such functions are called pure virtual functions and are denoted by the following notation

```
virtual void print() =0;
```

in the base class. A class with one or more pure virtual functions is an Abstract Class.

5.3 Redefining operators

If you need to redefine operators remember to redefine then consistently (if you redefine '+' don't forget '+=') and remember that you can't change precedence order. The default assignment operator does a simple copy of members, which might not be what you want.

p.198

Examples of redefining operators are in most books. Some things to remember when redefining assignment operators are

Deitel, p.474, Lippman, p.737

- that reference parameters help to overload operators efficiently (objects aren't copied) while keeping their use intuitive (pointers would require the user to supply addresses of objects).
- to deal with situations where a variable is assigned to itself. A pointer/reference to the object on the right of the = will be given to the function explicitly. A pointer to the object that the function is a member of is supplied implicitly to all non-static member functions. It's called this, so if this equals the supplied pointer, you'd usually want to do nothing.
- to return a const. This catches errors like (i+j)=k
- to return *this so that assignments can be chained (i.e. i=j=k becomes possible)

5.4 A class definition example

The following example highlights some of the more subtle issues associated with Constructors and Destructors.

It's the job of Constructors to allocate the resources required when new objects are created. If these are created using **new** then the Destructor should free the resources to stop memory being wasted. For example, if we want to store information about criminals we might define an object as follows

```
class criminal {
  string name;
  char* fingerprint;
  int fingerprint_size;
}
```

where fingerprint points to an image. The memory (if any) allocated for the image would be freed by the destructor.

assignment operator

That works fine until the following kind of situation arises

```
void routine (criminal a)
{
   criminal b;
   b=a;
   ...
}
```

The assignment b=a copies the bytes of a to b, so the fingerprint field of both objects will be the same, pointing to the same memory. At the end of this routine criminal's destructor will be called for b, which will delete the memory that

b.fingerprint points to, which unfortunately is the same memory as a.fingerprint points to.

To cure this we need to redefine the assignment operator so that the new object has its own copy of the resources.

```
void criminal::operator=(criminal const &b)
{
  name=b.name;
  fingerprint_size=b.fingerprint_size;
  delete fingerprint;
  fingerprint = new char[fingerprint_size];
  for (int i=0;i<fingerprint_size;i++)
     fingerprint[i]=b.fingerprint[i];
}</pre>
```

Note that space used by an existing fingerprint is freed first before a new fingerprint image is created - memory would be wasted otherwise.

this

But problems remain. If the programmer writes a=a, the delete command above frees a.fingerprint, which we don't want to free. We can get round this by making use of the this variable, which is automatically set to be the address of the current object. If the code above is bracketted by if (this != &b) { ... } then it's safe.

There's another improvement that we can make. So that assignments like a=b=c can work, it's better not to return void.

```
criminal const& criminal::operator=(criminal const &b)
{
  if (this != &b) {
    name=b.name;
    fingerprint_size=b.fingerprint_size;
    delete fingerprint;
    fingerprint = new char[fingerprint_size];
    for (int i=0;i<fingerprint_size;i++)
        fingerprint[i]=b.fingerprint[i];
}
  return *this;
}</pre>
```

copy constructor

But there's still a problem! Suppose the programmer writes criminal a=b;. a is being created, so a constructor a called - not an assignment. Thus we need to write another constructor routine using similar ideas to those used in assignment. Note that in this case resources don't need deleting, and that this needn't be checked (because criminal a=a; is illegal).

Putting all these ideas together, and sharing code where possible we get

```
void criminal::copy (criminal const &b)
name=b.name;
 fingerprint_size=b.fingerprint_size;
 fingerprint = new char[fingerprint_size];
 for (int i=0;i<fingerprint_size;i++)</pre>
    fingerprint[i]=b.fingerprint[i];
}
void criminal::destroy()
delete fingerprint;
// Assignment Operator
criminal const& criminal::operator=(criminal const &b)
 if (this != &b) {
  destroy(this);
  copy(b);
 }
}
// Default Constructor
criminal()
  fringerprint=0;
  fingerprint_size=0;
}
// Copy Constructor
criminal(criminal const &b)
  copy(b);
}
// Destructor
void ~criminal()
  destroy(this);
}
```

This seems like a lot of work, but it's necessary if objects use pointers to resources. You might think that by avoiding the use of commands like a=a in your own code, you can save yourself the trouble of writing these extra routines, but sometimes the problem situations aren't obvious. For instance, the copy constructor is called when an object is returned or used as an argument to a routine. Better safe than sorry.

5.5 Redefining []

p.286

vector doesn't have range-checking by default, but if you use the member function vector::at(), out_of_range exceptions can be trapped, so you can add

 ${\tt out_of_range}$ checking by redefining [] in a class derived from vector, and using vector's constructors -

```
template<class T> class Vec: public vector<T> {
  public:
  Vec() : vector<T>() {}
  Vec(int s) : vector<T>(s) {}

T& operator[] (int i) {return at(i);}
  const T& operator[] (int i) const {return at(i);}
}
```

The following more complicated example creates a mapping (relating a string to a number) without using the Standard Library's map facility. It does a word-frequency count of the text given to it.

```
#include <iostream.h>
#include <stdio.h>
#include <string>
#include <vector>
// The Assoc class contains a vector of string-int Pairs.
class Assoc {
 struct Pair {
    string name;
   int val;
    // The following line is a constructor for Pair
    Pair (string n="", int v=0): name(n), val(v) {}
 };
  // create a vector of the Pairs we've just created
  vector <Pair> vec;
public:
 // redefine []
 int& operator[] (const string&);
 // a member function to print the vector out
 void print_all() const;
};
// This redefines [] so that a ref to the value corresponding to the
// string is returned if it exists. If it doesn't exist, an entry
// is created and the value returned.
int& Assoc::operator[] (const string& s)
// The next line's creating an appropriate iterator
// for the vector of Pairs
 for (vector<Pair>::iterator p=vec.begin(); p!=vec.end(); ++p)
     if (s == p->name)
        return p->val;
     else{
        vec.push_back(Pair(s,0));
        return vec.back().val;
}
```

```
void Assoc::print_all() const
{
for(vector<Pair>::const_iterator p=vec.begin(); p!=vec.end(); ++p)
    cout << p->name<<": " << p->val << endl;
}
int main()
{
string buf;
Assoc vec;
   while(cin>>buf) vec[buf]++;
   vec.print_all();
}
```

5.6 Redefining ()

p.287 Coplien p.165

This can be used to provide the usual function call syntax for objects that in some way behave like functions ("function objects" or "functors"). These are used by the Standard Library.

5.7 Redefining ->

p.289

p.612

Smart pointers are pointers that do something extra (e.g. increment a counter) when they are used.

6 Input/Output

As with C, Input/Output is not part of the language, but support is provided by a library. Most programs need to use #include <iostream>.

You may also need #include <fstream> for file I/O, #include <iomanip> for greater control over formatting, and #include <strstream> for I/O to and from strings.

6.1 Simple I/O

The following illustrates the use of putback() for an input stream. istreams also have an ignore function (is.ignore(5) would ignore the next 5 characters) and a peek() function which looks at the next character without removing it from the stream.

```
istream& eatwhite(istream& is) { char c;
  while(is.get(c)) {
    if (!isspace(c)) {
       is.putback(c);
       break;
```

```
return is;
}
}
```

The following illustrates the use of I/O to and from files. Given the name of 2 files on the command line (which are available to main as C-style character arrays), it does a file copy.

```
void error(string p, string p2="") {
  cerr<<p << ' ' ' << p2 << endl;
  std::exit(1);
}
int main (int argc, char* argv[]) {
  if (argc != 3) error("wrong number of arguments");

  std::ifstream from(argv[1]);
  if (!from) error("cannot open input file", string(argv[1]));

  std::ofstream to(argv[2]);
  if (!to) error("cannot open output file", string(argv[2]));

  char ch;
  while (from.get(ch)) to.put(ch);

  if (!from || !to) error("something strange happened");
}</pre>
```

You can force the screen/file output to be up-to-date by using

```
cout.flush() or cout << flush;</pre>
```

but this isn't usually necessary.

If you want to write or read raw (binary) data (rather than strings that represent numbers) you can use write, read and casts (section 7.1) to keep the compiler happy. The following program writes 100 random integers into a file then reads them back.

```
#include <iostream.h> #include <stdlib.h> // to use rand #include
<fstream.h>
int main() {

  ofstream outfile("myresults",ios::out|ios::binary);
  if (outfile.good() == false) {
    cerr << "Cannot write to 'myresults'" << endl;
    exit(1);
  }

  int num;
  for (int i=0; i<100; i++){
    num=rand();</pre>
```

```
outfile.write(reinterpret_cast<const char*>(&num), sizeof(num));
}
outfile.close();

ifstream infile("myresults");
if (infile.good() == false) {
   cerr << "Cannot open 'myresults'" << endl;
   exit(1);
}

int count=0;
while(infile.read(reinterpret_cast<char*>(&num), sizeof(num))) {
   cout << num << endl;
   count++;
}
cout << count << " numbers read in" << endl;
infile.close();
return 0;
}</pre>
```

6.2 Formatting

The way that text and numbers are output can be controlled.

p.626

```
#include <iostream.h> #include <iomanip.h> #include <cmath> int
main() {
   int i=10;
   cout << "i = " << i << " (default)\n";
   cout << hex << "i = " << i << " (hex)\n";

   double d = sqrt(7.0);
   cout << "d=sqrt(7.0)=" << d << endl;
   cout.precision(3);
   cout << "After cout.precision(3), d=" << d << endl;
   return 0;
}</pre>
```

There many other routines too, amongst them

```
cout.setf(ios_base::oct,ios_base::basefield); // set base to 8
const ios_base::fmtflags myopt = ios_base::left|ios_base::oct;
ios_base::fmtflags old_options = cout.flags(myopt); //set base to 8
// and alignment to left.
cout.precision(8); // set precision to 8
cout.setf(ios_base::scientific, ios_base::floatfield);
cout.width(4); // output at least four characters cout.fill('*');
// fill gaps with '*' cin.noskipws(); // don't skip white space
```

6.3 Stream Iterators

Iterators can be used on streams, providing an elegant way to integrate I/O with p.60 container classes. You've seen them already in the Standard Library section.

```
ostream_iterator<string> oo (cout); int main()
*oo = "Hello";
++oo;
*oo = "World";
```

6.4 Output of User-Defined types

One way to do this is by overloading the stream insertion operator. The following defines how complex numbers should be printed out -

```
ostream& operator<<(ostream&s, complex z) // returns ostream& so can
be chained {
  return s << '(' << z.real() << ',' << z.imag() << ')';
}</pre>
```

6.5 Input of User-Defined types

```
The following code reads in a complex number that's provided in the form (a,b) or (a) p.621
```

```
istream& operator>>(istream&s, complex &a) // returns istream& so
can be chained {
 double re=0, im=0;
 char c=0;
 s>>c;
 if (c== '(') {
     s>>re >> c;
     if (c == ',') s >> im >> c;
     if (c != ')') s.clear(ios_base::badbit);
 }
 else {
   s.putback(c);
   s>> re;
 if (s) a = complex(re,im);
return s;
}
```

6.6 String streams

stringstreams are streams that are attached to a string rather than a file and letting you use the same syntax as file I/O. They are defined in stream.

```
#include <iostream.h>
#include <string>
#include <sstream>

int main() {
    int i = 7;
    string s1 = "He is ";
    string s2 = " years old";

    ostringstream ostring;
    ostring << s1 << i << s2;

    cout << "ostring =" << ostring;
    return 0;
}</pre>
```

7 Odds and Ends

7.1 Casts

C++ is strict about converting from one type to another - much stricter that C is. You can use C-style casting but it's not recommended - instances are hard to find in the code, and it's less type-safe. Try to use the least dangerous (most specific) casting alternative from those below

const_cast - used to remove the const qualifier.

dynamic_cast - does careful, type-sensitive casting at run time. Can't deal with
 void*.

reinterpret_cast - produces something that has the same bit pattern as the original.

static_cast - doesn't examine the object it casts from at run time. This is fast
if it's safe - and the compiler should tell you if it isn't safe. Can deal with
void*. static_cast can be used to reverse any of the implicit conversions
(like int to float).

To convert from a const void * to a File_entry** (a common kind of thing to do in C) I had to do

```
File_entry**fe2=
reinterpret_cast<File_entry**>(const_cast<void*>(entry2));
```

7.2 Limits

Use <climits> to access information on the system's limits. E.g. to check if a long variable can fit into a short you could try

7.3 Performance

The quality of the compiler and libraries can greatly affect the speed of the resulting code, but there's a lot you can do to help.

- Read about the available optimiser options. On HP's for example, using '+O4' instead of no optimisation can speed up some code by orders of magnitude.
- Try not to use call-by-value for big objects. Unless you need to change the
 object, use a reference to a const value
- Some C++ features have compile time implications, others have run time, program size or debugging implications. For example, making a function virtual can add 15% to the cost of a function call whereas templates have no runtime implications. They do, however, make things more difficult for debuggers and compilers. The Standard Template Library, for example, avoids virtual functions for performance reasons.
- Inlined routines are faster, but they'll bloat the code. Note that a member function defined in the class declaration is automatically inline. In particular, note that an inline destructor can be inserted at each exit point of a function.
- Though Standard Library algorithms like reverse work on both list and vector containers, the choice of container is still important for performance.
- Though vectors can grow, it's more efficient to create them with their maximum size.
- Try to create and initialise a variable in one operation.

7.4 Maths

If you're using any of the maths routines (sqrt, sin, etc) remember that you'll need to include cmath to declare the routines.

Before you start writing much maths-related code, check to see that it hasn't all been done before. Many maths routines, including routines that offer arbitrary precision are available from netlib, http://www.hensa.ac.uk/netlib/master/readme.html.

Before you do any heavy computation, especially with real numbers, I suggest that you browse through a Numerical Analysis book. Things to avoid are

- Finding the difference between very similar numbers (if you're summating an alternate sign series, add all the positive terms together and all the negative terms together, then combine the two).
- Dividing by a very small number (try to change the order of operations so that this doesn't happen).
- Multiplying by a very big number (use logs).

Common problems that you might face are :-

Testing for equality: Real numbers are handled in ways that don't guarantee expressions to yield exact results. Just as in base 10 to 2 decimal places, 3*(10/3) doesn't equal 10, so computer arithmetic has its limitations. It's especially risky to test for exact equality. Better is to use something like

```
d = max(1.0, fabs(a), fabs(b))
```

and then test fabs(a - b) / d against a relative error margin. Useful constants in <climits> are FLT_EPSILON, DBL_EPSILON, and LDBL_EPSILON, defined to be the smallest numbers such that

```
1.0f + FLT_EPSILON != 1.0f
1.0 + DBL_EPSILON != 1.0
1.0L + LDBL_EPSILON != 1.0L
```

respectively.

Avoiding over- and underflow: You can test the operands before performing an operation in order to check whether the operation would work. You should always avoid dividing by zero. For other checks, split up the numbers into fractional and exponent part using the frexp() and ldexp() library functions and compare the resulting values against HUGE (all in <cmath>).

Floats and Doubles: You can use the information in imits> or use sizeof(double), etc to compare the size of float, double and long double.

- Keep in mind that the double representation does not necessarily increase the *precision* over float. Actually, in most implementations the worst-case precision decreases but the *range* increases.
- Do not use double or long double unnecessarily since there may a large performance penalty. Furthermore, there is no point in using higher precision if the additional bits which will be computed are garbage anyway. The precision one needs depends mostly on the precision of the input data and the numerical method used.

```
#include <iostream.h> #include <stdio.h>
int main(int argc, char* argv[]) { float f1; double d1; long double
ld1;

f1=d1=ld1=123.45678987654321; cout.precision(50); cout << "f1=" <<
f1 << ", f1**2=" << f1*f1 << endl; cout << "d1=" << d1 << ", d1**2="
<< d1*d1 << endl;
//The following doesn't work on HPs!</pre>
```

```
//cout << "ld1=" << ld1 << "ld1**2=" << ld1*ld1 << endl;
printf("ld1=%25.25Lf, ld1*ld1=%25.25Lf\n", ld1, ld1*ld1);
return 0; }</pre>
```

Infinity: The IEEE standard for floating-point maths recommends a set of functions to be made available. Among these are functions to classify a value as NaN, Infinity, Zero, Denormalized, Normalized, and so on. Most implementations provide this functionality, although there are no standard names for the functions. Such implementations often provide predefined identifiers (such as _NaN, _Infinity, etc) to allow you to generate these values.

If x is a floating point variable, then (x != x) will be TRUE if and only if x has the value NaN. Some C++ implementations claim to be IEEE 748 conformant, but if you try the (x!=x) test above with x being a NaN, you'll find that they aren't.

The following sythesises a NaN on HP machines, then uses isnan().

```
#include <iostream.h> #include <cmath>
double make_a_NaN () { double ret; char* pointer =
reinterpret_cast<char*>(&ret); int i;
// IEEE spec for doubles on HPs
//
     0 : sign bit
     1-11: exponent
   12-63: fraction
// For QNaNs on HPs
// set 1-11 to 1, 12=0, rest to 1
for (i=0; i<8; i++)
  *(pointer+i) = 255;
*(pointer+1)= 247;
return ret; }
int main(int argc, char* argv[]) { double d;
d=make_a_NaN (); if (isnan(d))
  cout << d << " is a nan" << endl;</pre>
  cout << d << " is not a nan" << endl;</pre>
return 0;
}
```

An increasing amount of maths work is being done with C++. One development is the *Template Numerical Toolkit* built around the Standard Library.

7.5 Hardware Interfacing: bit operations and explicit addresses

If you're interfacing with hardware and need to operate on bits you can use bitset but you may prefer to use C++'s low-level operations.

- Setting a bit: Suppose you wanted to set bit 6 of i (a long, say) to 1. First you need to create a mask that has a 1 in the 6th bit and 0 elsewhere by doing '1L<<6' which shifts all the bits of the long 1 left 6 bits. Then you need to do a bit-wise OR using 'i = i | (1L<<6)'.
- Unsetting a bit: Suppose you wanted to set bit 6 of i (a long, say) to 0. First you need to create a mask that has a 0 in the 6th bit and 1 elsewhere by doing '1L<<6' then inverting the bits using the ~ operator. Then you need to do a bit-wise AND using the & operator.

The whole operation is 'i =i & ~(1<<6)' which can be contracted to 'i &= ~(1<<6)'.

Creating a mask:- In \mathcal{X} graphics, masks are often created each of whose bits represent a option that is to be selected in some way. Each bit can be referred to using an alias that has been set up in an include file. For example, a mask which could be used in a call to make a window sensitive to key presses and buttonpresses could be set up by doing

```
unsigned int mask = KeyPressMask | ButtonPressMask ;
```

Suppose because of hardware considerations the i variable needed to be the value of memory location 2000. The following code will do what you want.

```
long *memory_pointer = reinterpret_cast<long*>(2000); long i =
*memory_pointer;
```

7.6 Using routines from other languages

7.6.1 C

When your C++ code is presented with the prototypes of C routines, the prototypes need to be bracketed by the following

```
#ifdef __cplusplus extern "C" { #endif ... #ifdef __cplusplus }
#endif
```

so that the code compiles.

7.6.2 Fortran

This is a rather machine-specific issue. Rudi Vankemmel (ankemme@imec.be) mentions some general points that are worth noting:-

- 1. Fortran uses a column wise storage of matrices while C++ stores them row wise. This means that when you want to parse a matrix from your C++ program to the fortran routine you must transpose the matrix in your program before entering the routine. Of course, any output from such a routine must be transposed again.
 - If you omit this step, then probably your program will run (because it has data to compute on) but it will generate wrong answers.
 - If you have the Fortran source code (of any routine) then on some platforms you may use compiler directives specifying that the Fortran compiler must use row wise storage. Some platforms support these directives. However watch out with this if you call the same routine from another Fortran routine/program.
- 2. Your Fortran compiler may add an underscore to the routine name in the symbol table. Hence in the calling C++ program you must add a trailing underscore! Otherwise the loader will complain about an undefined symbol.
- 3. Fortran passes its variables by reference. This means that you MUST give adresses in your calling C++ program.
- 4. Watch out especially with floats and doubles. Make sure that the size of the variable in the calling program is identical to the size in the Fortran routine.

7.7 bad habits to give up

C++ is a flexible language. You can write C++ that a C compiler could compile. You can even write in a style that isn't too distant from Fortran 77. But if you're a C programmer who wants to make the most of modern C++, the following points are worth bearing in mind

- Think in terms of objects rather than functions. Groups of objects are easier to organise (using inheritance) than are groups of functions.
- Use namespaces: functions can have shorter names; information hiding is easier; and it's easier to switch between different implementations. Use namespace rather than files to control scoping.
- Use references rather than pointers when you can.
- Use strings. You can convert between C and C++ strings

```
char cstring[]="a test";
string a_str;
a_str=string(cstring);
strcpy(cstring, a_str.c_str());
```

- Don't use NULL use 0
- Create variables just before first use. In particular, create for loop index variables within the loop construction.
- Use exceptions when the code that has to deal with a problem is far from the code that discovers the problem.
- Use const as much as possible. Note that in C++, const variables have internal linkage by default whereas in C, they have external linkage.

- Use enum
- Don't use type-identifer fields in structures
- Avoid pre-processor macros. const, inline, template and namespace replace p.161 most of #define usage, leading to stronger typing and better control of scope. For example

```
const int answer = 42; template<class T> inline T min(T a, T b)
{return (a<b)?a:b;}</pre>
```

• Avoid static except within functions.

```
// better than a global
int & use_count() { static int uc =0; return uc; }
or use nameless namespaces
namespace { class X{}; void f(); // like a static int i; }
```

7.8 Non-essentials (Things you probably don't need to know yet)

7.8.1 virtual inheritance

Inheritance can be private (where even the public fields of the base class are treated as private), public (where the base class determines visibility), or virtual. With virtual inheritance there is only one copy of each object even if (because of multiple inheritance) the object appears more than once in the hierarchy. In the following example, derived1a and derived1b each contain a base object, but derived2 contains just one i field.

```
#include <iostream.h>

class base{ public:
    int i;
};

class derived1a: virtual public base { public:
    int j;
};

class derivedb: virtual public base { public:
    int k;
};

class derived2: public derived1a, public derived1b{ public:
    int product() {return i*j*k;}
};

main() { derived2 obj; obj.i = 10; obj.j = 3; obj.k = 5;

cout << "product is" << obj.product() << '\n'; return 0; }</pre>
```

7.8.2 typeid

p.414

In C++ you can identify the type of an object dynamically using RTTI (run-time type information). Given a type name, typeid returns a reference to a type_info object (in <type-info>). Can also give it an expression

```
#include <typeinfo> void g(Component* p) { cout <<
typeid(*p).name();
}</pre>
```

7.8.3 virtual destructors

p.422

p.409

You can't have virtual constructors, but you can have virtual destructors. They're Coplien p.140 not quite ordinary functions - no pointer to them is possible, for example).

7.8.4 Auto pointers

p.367, Deitel p.688, Lippman

 ${\tt auto_ptr}$ in ${\tt <memory>}$ - object pointed to will be deleted when pointer goes out of scope

7.8.5 operator functions

An operator function can be a member or non-member. The assignment, subscript, call and member selection operators are required to be class member functions.

7.8.6 union

A union is like a struct except that the fields occupy the same memory location with enough memory allocated to hold the largest item. The programmer has to keep a note of what the union is being used for. What would the following code print out?

```
... union person {
    int age;
    int height;
    char surname[20];
} fred;

fred.age = 23;
  fred.height = 163;
  cout << "Fred is " << fred.age << "years old\n"; ...</pre>
```

If fred started at memory location 2000, then fred.age, fred.height and fred.surname would all begin at memory location 2000 too, whereas in a struct the fields wouldn't overlap. So setting fred.height to 163 overwrites fred.age (and the 1st 4 characters of fred.surname) making fred 163 years old.

7.8.7 Non-type template parameters

Values as well as types can be used as template parameters.

```
template < class T, int size> class MyArray { ...
```

This lets the template create arrays of a fixed size (good for performance reason) but it means that a new piece of code will be created for each different class/size combination used.

8 Program Development

Stroustrup writes that the last section of his book aims

p.691

to bridge the gap between would-be language-independent design and programming that is myopically focussed on details. Both ends of this spectrum have their place in a large project, but to avoid disaster and excessive cost, they must be part of a continuum of concerns and techniques.

Programs vary considerably in their composition. I've seen these figures quoted

- Coding takes 10% of the total time. Debugging takes 50%.
- The Graphical User Interface is 80% of the code
- Error handling can be 50% of the code

Complexity is the enemy, so

- Divide and conquer.
- Use modules namespaces or files (helps the optimiser too).

Don't re-invent the wheel

- Copy models
- Adapt existing parts
- When making new parts design them for re-use

8.1 Style

It helps if you decide upon a uniform style for writing code. It's common to suggest that for all except the most trivial classes it's wise to define

Coplien p.38-45

• a void constructor -

• a copy constructor - to create a new object using values from an existing one. Use call-by-reference to avoid infinite recursion.

Deitel p.483

• the assignment operator - that returns a reference.

And then there's the "the rule of three" - if you write any one of a copy constructor, copy assignment operator or destructor, then you will almost certainly need to write all three for your class to function properly.

Stanley Lippman in Dr.Dobb's Journal, October 99, (p.40) noted that unnecessary definition of these functions is likely in practise to make the code bigger and/or slower - he got a 40% speed improvement by removing all 3 from a piece of code, the compiler's default alternatives being more efficient.

When deriving classes

Coplien p.192

- if using public inheritance, most base class member functions should be declared virtual to ensure that the derived class customisations will override the base class behaviour even in a context where a base class object is expected.
- use virtual inheritance if you are not especially concerned about performance or if you might use multiple inheritance later.

8.2 Makefiles

If you have many source files you don't need to recompile them all if you only change one of them. By writing a makefile that describes how the executable is produced from the source files, the make command will do all the work for you. In the 1A/1B courses makefiles were created by the xcc^1 program, but you may well need to write your own eventually.

The following makefile says that pgm depends on two files a.o and b.o, and that they in turn depend on their corresponding source files (a.cc and b.cc) and a common file incl.h:

```
pgm: a.o b.o
aCC a.o b.o -o pgm
a.o: incl.h a.cc
aCC -Aa -c a.cc
b.o: incl.h b.cc
aCC -Aa -c b.cc
```

Lines with a ':' are of the form

target : dependencies

make updates a target only if it's older than a file it depends on. The way that the target should be updated is described on the line following the dependency line (Note: this line needs to begin with a TAB character).

¹http://www-h.eng.cam.ac.uk/help/tpl/languages/xccmake.html

Here's a more complex example of a makefile for a program called dtree. First some variables are created and assigned. In this case typing 'make' will attempt to recompile the dtree program (because the default target is the first target mentioned). If any of the object files it depends on are older than their corresponding source file, then these object files are recreated.

The targets needn't be programs. In this example, typing 'make clean' will remove any files created during the compilation process.

```
# Makefile for dtree DEFS = -02 -DSYSV
CFLAGS = \$(DEFS) - 0
LDFLAGS = CC = aCC
LIBS = -lmalloc -lXm -lXt -lX11 -lm
BINDIR = /usr/local/bin/X11 MANDIR = /usr/local/man/man1
OBJECTS_A = dtree.o Arc.o Graph.o
                                     #using XmGraph
ARCH_FILES = dtree.1 dtree.cc Makefile Dtree Tree.h TreeP.h \
dtree-i.h Tree.cc Arc.cc Arc.h ArcP.h Graph.cc Graph.h GraphP.h
dtree: $(OBJECTS_A)
     $(CC) -o dtree $(LDFLAGS) $(OBJECTS_A) $(LIBS)
 Arc.o: Arc.cc
     $(CC) -c $(CFLAGS) Arc.cc
Graph.o:
            Graph.cc
     $(CC) -c $(CFLAGS) Graph.cc
dtree.o:
            dtree.cc
     $(CC) -o dtree.o -c $(CFLAGS) -DTREE dtree.cc
install: dtree dtree.1
     cp dtree $(BINDIR)
     cp dtree.1 $(MANDIR)
clean:
    rm -f dtree *.o core tags a.out
```

8.3 Debugging

Code Complete by Steve McConnell (Microsoft Press, 1993) is the book to read. It has very useful sections on testing and debugging, and quotes results from investigations of software quality assurance. On p.567 it notes that the industry average for code production is 8-20 lines of correct code per day. On p.610 it notes that industry average experience suggests that there are 15-50 errors per 1000 lines of delivered code. The recommendation is to design and code defensively - it saves time in the end.

C++ is a strongly-typed language with many features to help write safe code, but you still need to be cautious

• Let the compiler help you as much as possible! Many compilers generate

warning messages if you ask them to.

- Assume when you're writing your program that it won't be bug-free. Write it so that you (and others) can easily debug it: make routines small and control flow simple.
- Concrete examples are easier to debug. You can make them into a template once they're working.
- Write a test suite (for you and future users)
- Don't get stuck at one level zoom in and pan out. Your code should be understandable locally (parts should be as isolated from other parts as possible) and at the top level.
- Write "defensive" code. Always assume the worst.
- It's not uncommon for beginners to prove to themselves on paper that their broken code is correct and the compiler is wrong. Add cout statements to print out intermediate values and test assertions.
- If you're using floating point arithmetic, check divisions to see if you're dividing by zero.
- Check that you're not going off the end of arrays.
- To comment-out large chunks of code bracket it with

```
#if 0 ... #endif
```

See the Debugging handout² for details of the wdb debugger³.

8.4 Common Difficulties and Mistakes

 ${\bf Obscure \ Error \ Messages} \ - \ {\bf small \ errors \ in \ a \ simple-looking \ line \ can \ produce }$ complicated messages like the following

```
Error 226: "set1.cc", line 16 # No appropriate function found for
call of
   'operator <<'. Last viable candidate was "ostream &ostream::operator
   <(char)" ["/opt/aCC/include/iostream/iostream.h", line 509]. Argument of
   type 'class set<int,less<int>,allocator>' could not be converted to
   'char'.
      cout << "s1 = " << s1;</pre>
```

The ^^^ symbols show which part of the line is at fault. In this case the compiler can't narrow down the problem, so next read the first (easiest) part of the error message. There's something wrong with the use of <<. Remember that in C++ many functions can be invoked by an operator - it all depends on the number and type of operands. In this case s1 (a set) isn't something that there's a matching function for - hence the error message. The compiler, trying to be helpful, gives the next best option - a function tied to << that can deal with a char.

²http://www-h.eng.cam.ac.uk/help/tpl/languages/debug/debug.html

³http://www-h.eng.cam.ac.uk/help/tpl/languages/debug/node5.html

Another example: the line double d = sqrt(4); produces the following error because the integer given to sqrt has to be promoted to a real, but the compiler doesn't know what kind of real.

```
Error 225: "foo.cc", line 6 # Ambiguous overloaded function call;
more than
```

one acceptable function found. Two such functions that matched were "long double sqrt(long double)" ["/opt/aCC/include/cmath", line 107] and "float sqrt(float)" ["/opt/aCC/include/cmath", line 57].

- Obscure declarations and definitions C++ has fewer keywords than many languages but it makes up for this by having many meaning attached to a symbol. For example '<' is used in #include lines, cout, in template definitions as well as meaning 'less-than'. This makes deciphering declarations hard. c++decl can sometimes help.
- **Deriving from Container Classes** the container classes weren't designed to act as base classes: they don't have virtual functions. Use them as members of other classes instead.
- Object creation The first 2 lines below create a string variable s. The 3rd doesn't create an empty string it declares a function s that returns a string.

```
String s; String s("initial"); String s();
```

 $\begin{tabular}{ll} \textbf{Input and newline characters} & \textbf{-} & \textbf{If you try to get a character then a string from the user with} \\ \end{tabular}$

```
cout << "Type a character: "; cin >> ch; cout << "Type a string: ";
cin.getline(str,20);</pre>
```

you're likely to get an empty string because the >> operator leaves the typed newline in the input stream. One way round this is to use istream::ignore(INT_MAX, '\n');

9 CImg, an image processing library for C++

The CImg library is an image processing library, designed for C++ programmers. It provides useful classes and functions to load/save, display and process various types of images.

9.1 library structure

The CImg Library consists in a single header file CImg.h providing a set of C++ template classes that can be used in your own sources, to load/save, process and display images or list of images.

Very portable (Unix/X11, Windows, MacOS X, FreeBSD,...), efficient, simple to use, its a pleasant toolkit for coding image processing applications in C++.

The header file CImg.h contains all the classes and functions that compose the library itself. This particularly means that:

- No pre-compilation of the library is needed, since the linking of the CImg functions is done at the same time as the linking of your own C++ code.
- No complex dependencies have to be handled: Just include the CImg.h file, and you get a working C++ image processing toolkit.
- The compilation is done on the fly: only CImg functionalities actually used by your program are compiled and appear in the executable. This leads to very compact code, without any unused code.
- Class members and functions are inlined, leading to better performance during the program execution.

The CImg Library is structured as follows:

All library classes and functions are defined in the namespace cimg_library.
 This namespace encapsulates the library functionalities and avoid any class name collision that could happen with other includes. Generally, one uses this namespace as a default namespace:

```
#include "CImg.h"
using namespace cimg_library;
```

- The namespace cimg_library::cimg defines a set of low-level functions and variables used by the library. Documented functions in this namespace can be safely used in your own program. But, don't use the cimg_library::cimg namespace as a default namespace, since it contains functions whose names are already defined in the standard C/C++ library.
- The class cimg_library::CImg<T> represents images up to 4-dimensions wide, containing pixels of type T (template parameter). This is actually the main class of the library.
- The class cimg_library::CImgList<T> represents lists of cimg_library::CImg<T> images. It can be used for instance to store different frames of an image sequence.
- The class cimg_library::CImgDisplay is able to display images or image lists into graphical display windows. As you may guess, the code of this class is highly system-dependent but this is transparent for the programmer, as environment variables are automatically set by the CImg library
- The class cimg_library::CImgException (and its subclasses) are used by the library to throw exceptions when errors occur. Those exceptions can be catched with a try { ..} catch (CImgException) { .. } construct. Subclasses define precisely the type of encountered errors.

9.2 CImg, Hello world

.

Below is a very simple code that creates a *Hello World* image.

```
#include "CImg.h"
using namespace cimg_library;
int main() {

    CImg<unsigned char> img(640,400,1,3);
    // Define a 640x400 color image with 8 bits per color component.

    img.fill(0);
    // Set pixel values to 0 (color : black)

    unsigned char purple[] = { 255,0,255 };
    // Define a purple color

    img.draw_text(100,100,"Hello World",purple);
    // Draw a purple "Hello world" at coordinates (100,100).

    img.display("My first CImg code");
    // Display the image in a display window.

    return 0;
}
```

9.3 compiling a CImg application

The CImg library is a very light and user-friendly library. Only standard system libraries are used. It avoids complex dependencies and problems with library compatibility. The only thing you need is a (quite modern) C++ compiler:

• g++ (Linux version): Use the following command to compile and link a CImg application with g++, on Linux:

```
g++ -o hello_word.exe hello_world.cpp -02 -L/usr/X11R6/lib -lm -lpthread -lX11
```

• g++ (MingW windows version): Use the following command to compile and link a CImg application with g++, on Windows:

```
g++ -o hello_word.exe hello_word.cpp -02 -lgdi32
```

10 Glossary

- Abstract Class a class with at least one pure virtual function.
- Abstract Data Type (ADT) An abstract class.
- Adapters ways to adapt existing predicates.
- Algorithm general-purpose routines for use with container classes.
- Bag a multiset.
- Cast explicit conversion of an object type.
- Container A class that can hold other objects.
- Iterator Something that can point to an object in a container.
- Multiple Inheritance When a class has more than one base class.
- Namespace a scoping mechanism that can scan files.
- Overloading When calling a function runs different code . according to the types and number of arguments provided.
- Polymorphism not having to worry about the type of object you're dealing with.
- Predicate a function object that returns a bool.
- Pure Virtual function a function that *must* be over-ridden in a derived class.
- The Standard Library classes, algorithms, and function objects providing support for strings, vectors, lists, maps, strings and random numbers.
- Template A class that can be "filled in" with various types.
- Virtual function a function that can be over-ridden in a derived class.
- Volatile a variable is volatile if it might change beyond control of the program.
